

Abstract

Short reads based *de-novo* assembly is challenging for complex genomes with variable homologous regions and considerable repetitive elements. Long-Mate Paired (LMP) libraries of different jumping sizes offer potential solutions to bring short reads of different gap sizes into contigs and improve the intactness of the draft genome assembly. Furthermore, LMP sequences can facilitate the ordering of contigs into scaffolds and detect structural variations like indel and translocations. Here, we report the developments of two complementary LMP library construction methods: Cre-Lox Inverse PCR-Illumina Paired-End (CLIP-PE) and Ligation Free Paired-End (LFPE). In CLIP-PE, libraries are created by ligation of biotin-LoxP adaptors to the ends of fixed sizes gDNA and circularized by Cre recombinase mediated intra-molecule recombination. The circularized product is fragmented by a selection of 4-base pair cutting enzyme (*NlaIII*, *MseI* or *HpyCH4IV*). The ends of fragmented DNA are self-ligated, biotin-streptavidin selected and enriched by inverse PCR. Mate-Pairs generated by CLIP-PE libraries are identified by the 4-base pair enzyme cutting site. LFPE libraries are created by ligation of internal adaptors lacking 5' phosphate to the ends of gDNA fragments and circularization by hybridization. The circularized product is nick translated, digested by T7 Exonuclease/ S1 Nuclease into short paired tags of fix span sizes, biotin-streptavidin selected and finally, enriched by PCR. Mate-Pairs generated from LFPE libraries are identified by the internal linker junction site. Two organisms *Mycosphaerella fijiensis* CIRAD86 and *Phycomyces blakesleeanus* NRRL1555 were selected to test the effectiveness of these two LMP library creation methods. Sequencing data generated from the two methods were analyzed to evaluate the resulted assembled genomes for their qualities, coverage, redundancy, bias and accuracy. We conclude that both methods have their unique advantages and disadvantages for various genome assembly applications.

CLIP-PE and LFPE Library Construction Approaches

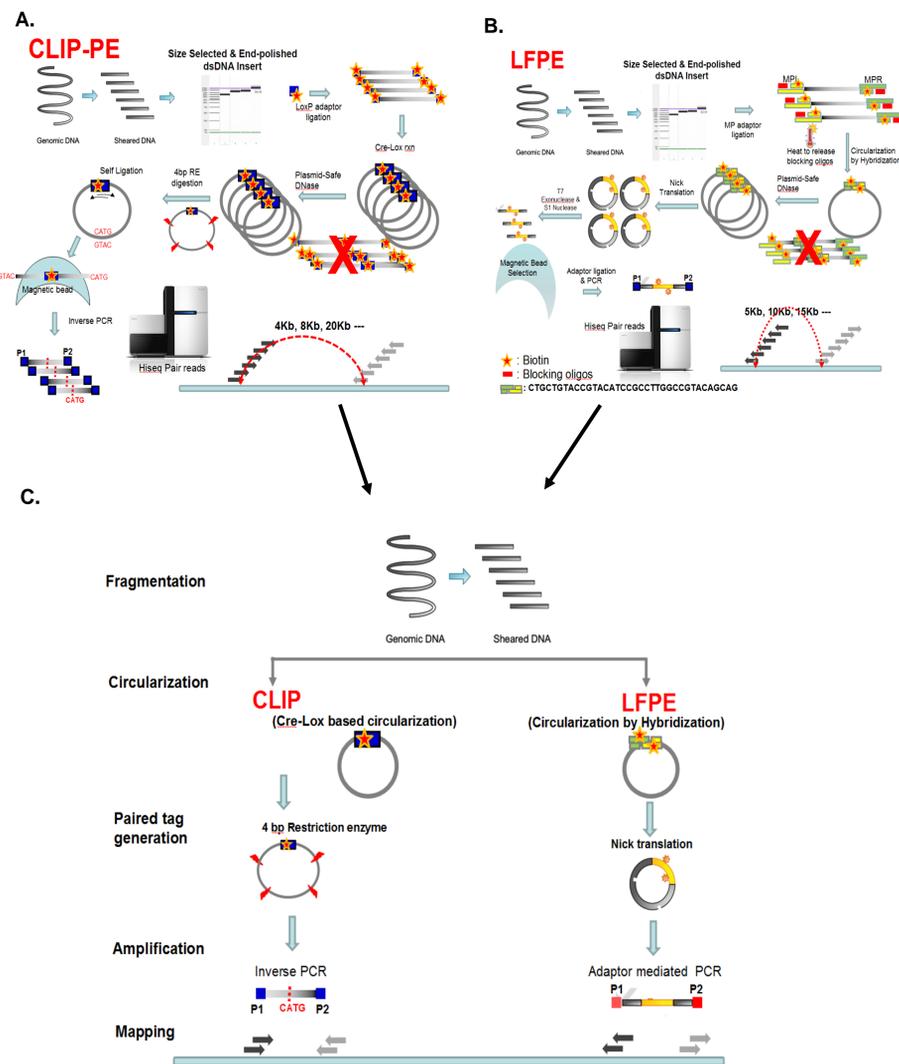

Figure 1. A schematic representation of CLIP-PE and LFPE library construction process (A and B). CLIP-PE is a Cre-LoxP recombination system based circularization, using a 4-bp restriction enzyme followed by inverse PCR to generate long paired-end tags. Circularization of LFPE is based on a ligation free hybridization of internal adaptors. Long pair-end tags are created by Nick Translation, T7-Exonuclease/S1 Nuclease following circularization (C). The organisms *Phycomyces blakesleeanus* NRRL1555 and *Mycosphaerella fijiensis* CIRAD86 were carefully selected for this experiment to compare the CLIP-PE and LFPE protocols.

Insert Size Distribution

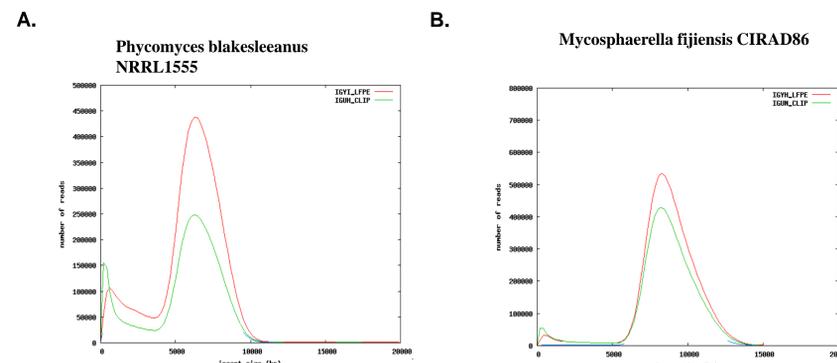

Figure 2. Histogram of insert sizes from *Phycomyces blakesleeanus* NRRL1555 and *Mycosphaerella fijiensis* CIRAD86 6-8 kb libraries. The distribution of insert lengths were determined by aligning the reads to the reference genome using the BWA aligner. The genomic DNA were sheared by hydroshear and ran on agarose gel. The samples were size selected between 6-8kb and divided evenly for CLIP-PE and LFPE library creation. Therefore, the size distribution for the two process is expected to be identical.

Coverage Distribution

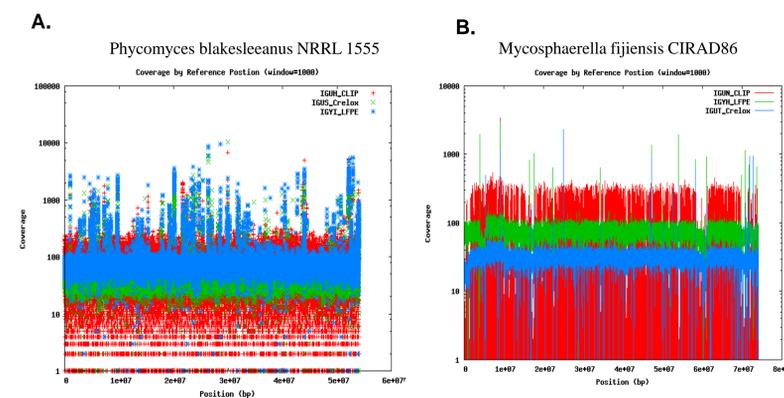

Figure 3. The above chart describes the total coverage when each library were mapped back to the reference. According to the above chart, sequencing data generated from LFPE library creation process yield a tighter coverage, were as CLIP-PE has a broad range. The third library, Cre-lox based, is not a part of the experiment and is not covered in the poster.

Redundancy

Organism	Library	Type	Size (kb)	Reads (M)	Net Reads (M)	Redundant (%)
<i>Phycomyces blakesleeanus</i> NRRL1555	IGUH	CLIP	8	58.5	33.6	62.9
	IGYI	LFPE	8	78.9	59.7	30.3
<i>Mycosphaerella fijiensis</i> CIRAD86	IGUN	CLIP	8	66.4	40.6	55.7
	IGYH	LFPE	8	74.7	63.2	15.7

Figure 4. The libraries created by CLIP-PE and LFPE process for *Phycomyces blakesleeanus* NRRL1555 and *Mycosphaerella fijiensis* CIRAD86 were pooled based on organism and sequenced 2 x150 run on Illumina HiSeq platform, sharing one lane for each organism. The idea is to generate equal amount of reads for a fair comparison of redundancy between the two process. Non-redundant pairs are those that have unambiguous mapping coordinates. According to the data-chart and graphs, LFPE library creation is significantly less redundant for both organisms.

Assembly Metrics

Library Type	Contigs	Scaffolds	CL50	SL50		
<i>P. blakesleeanus</i> NRRL1555	--	371	81	368	1500	Nuclear Genome Assembly v2.0
CLIP-PE	2920	690	42	339		
LFPE	2804	479	50	526		
<i>M. fijiensis</i> CIRAD86	--	778	56	211	5900	Nuclear Genome Assembly v2.0
CLIP-PE	4944	3817	27	64		
LFPE	4390	538	50	443		

Figure 5. Nuclear Genome Assembly v2 is an improved assembly produced by the JGI Finishing Pipeline. Assembly v2 reports *P. blakesleeanus* NRRL1555 has 81 scaffolds and *M. fijiensis* CIRAD86 has 56 scaffolds. The N50 contig and scaffold score using only CLIP-PE library for assembly is much lower than LFPE library. Assembly using LFPE reduce scaffold size and slightly improve the number of contigs.

Quality of Reads

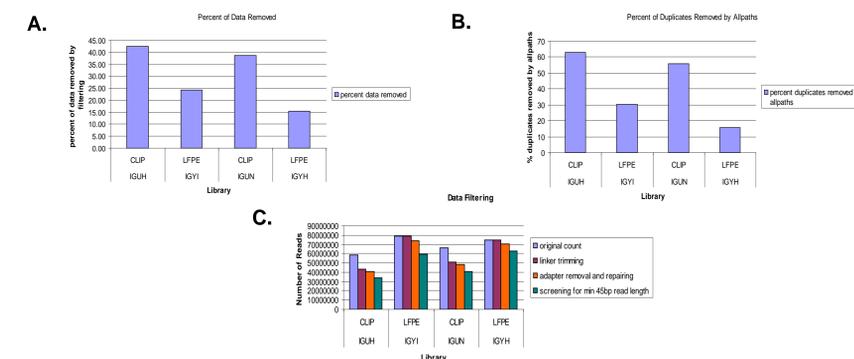

Figure 6. The above graphs detail of how much data is left after each filtering step: total percent data removed from filtering (A and B) and percent duplicates removed by AllPaths (C). The minimum read length distributions is determined after all filtering steps, which includes middle linker trimming, filtering out artifacts and removing singlet reads, and screening out pairs with one read is less than 45 bp (C).

Annotation Results

Organism	Library	Type	Size (kb)	Reads (M)	Net Reads (M)	Redundant (%)
<i>Phycomyces blakesleeanus</i> NRRL1555	IGUH - CLIP-PE	run.std_50_jmp_50	8	58.5	33.6	62.9
	IGYI - LFPE	run.std_50_jmp_50	8	78.9	59.7	30.3
<i>Mycosphaerella fijiensis</i> CIRAD86	IGUN CLIP-PE	run.std_50_jmp_50	8	66.4	40.6	55.7
	IGYH LFPE	run.std_50_jmp_50	8	74.7	63.2	15.7

Figure 7. The annotation results provide a detailed comparison of the quality of each library.

Conclusions

CLIP-PE and LFPE 8kb libraries were created in parallel; however, data show LFPE libraries have better coverage/complexity distribution, uniqueness, and assembly compared with CLIP-PE libraries. However, both library creation processes have limitations. CLIP-PE is limited as it relies on 4-bp restriction site which can introduce coverage bias in genomes with extremely high or low GC. Furthermore, there may be concerns of potential gaps in genome coverage if the restriction enzyme site is unevenly distributed throughout the genome. LFPE is hybridization mediated circularization followed by nick translation which makes the process sensitive to time and temperature. Circularization can be less efficient as the target insert size increase to above 10kb due to the nature of self-hybridization of internal adaptors. Additionally, DNA quality of starting material is far most important. Samples with poor quality DNA may not produce a high quality library as a result of nicks within the genome inhibiting nick translation reaction. CLIP-PE on the other hand can be modified to replace enzyme restriction with random shearing (process is under testing) to eliminate coverage biases. LFPE process produces better quality sequencing data, however process is not scalable and not robust as compared to CLIP-PE libraries.
